Acknowledgments

First and for most, I would like to thanks my advisor Dr. Fikere Enquoselassie for his unreserved support and constructive comments through out the preparation of this thesis paper.

My thank also to the national defense force University College for funding this thesis research paper.

My special thank and appreciation to those who agree to participate in the study and to all who participate in the data collection process of the study.

Last but not least, my special thank goes to AIDS resource center.

List of abbreviations

ANC – antenatal care.

AIDS – acquired immunodeficiency syndrome.

HIV – human immune-deficiency virus.

MCH – mother and child health care.

MTCT – mother to child transmission.

PMTCT – prevention of mother to child transmission.

UNAIDS – United nation program on AIDS.

VCT – Voluntary counseling and testing.

TASO – The AIDS support organization.
ABSTRACT

Background Mother-to-child transmission (MTCT) is by far the largest source of HIV infection in children below the age of 15 years. The virus may be transmitted during pregnancy, child birth or breast feeding. Globally 2.7 million children under the age of 15 years have died of AIDS since the beginning of the epidemics. Over 9 in 10 were infected by their mothers. For many years little was known about preventing transmission of HIV infection from mother to child. Recently however, many interventions are available to reduce mother to child transmission, such as anti retroviral drug and avoidance of breast feeding. For women to take advantage of measures to reduce transmission, they need to know their HIV status. Despite this fact many women are not willing to take voluntary HIV counseling and testing.

Objective The main objective of the study is to identify factors determining acceptance of voluntary HIV testing among pregnant women at army hospitals in Addis Ababa.

Method Unmatched case control study was conducted on 88 acceptors and 176 non-acceptors of VCT using structured pretested questionnaire from December 2004 to January 2005, at army hospitals in Addis Ababa.

Results Among socio-demographic factors the odds of VCT acceptance was higher among better educated, married, with higher income women and among women whose husbands live at home. Women who had better knowledge of VCT and MTCT and women with at least two ANC visit had significantly higher VCT acceptance than their counterparts.
Adjusted for socio-demographic and some reproductive characteristics, VCT acceptance was significantly associated with knowledge about MTCT (OR= 7.34, 95% CI= 3.44, 15.67), previous VCT experience (OR= 2.51, 95% CI= 1.03, 6.17) and husbands residence (at home) (OR= 4.97, 95% CI = 2.15,11.46).

Conclusions and recommendation

Education of the mother, knowledge of MTCT and VCT and partner participation were important factors of VCT acceptance. Health education targeted on pregnant women on PMTCT and VCT would have paramount importance using different sources.

**Key words**  acceptance, HIV testing, pregnant women, antenatal care
1. Introduction

Knowledge about HIV/AIDS has been expanding in the past two decades, as has the number of infections globally. The routes of HIV spread are now firmly established, and includes sexual contact, transfusion of infected blood or blood product and mother to child transmission (MTCT). Infection among women of reproductive age is undoubtedly on the rise, which underlies the potential for an increasing number of prenatal HIV infections (1).

In 2003 an estimated 630,000 children worldwide become infected with HIV; the vast majority of them during pregnancy, child-birth or breast-feeding. Africa remains by far the region worst affected by the HIV epidemic. The HIV prevalence varies considerably across the continent ranging from less than 1% in Mauritania to almost 40% in Botswana and Swaziland. More than one in five pregnant women are HIV infected in most southern Africa countries, while else where in sub-Saharan Africa median HIV prevalence in antenatal clinics exceeds 10% (2).

In Ethiopia over 80% of the cases of HIV are found between the age of 20 and 49 years, the most economically active group of the population. Survey from the ministry of health showed that certain population groups are at risk more than others. Commercial sex workers, long distance truck drivers and the military were found to have been the most severely affected. In addition sero prevalence data based on ANC surveillance in Addis Ababa among 15-24 years pregnant women showed that HIV prevalence is about 11% in 2003 after having a peak at approximately 24% in 1995 (3).
The risk of acquiring the virus from an infected mother to baby ranges from 15% to 25% in industrialized countries compared to 25% to 35% in developing countries; largely due to breast feeding practice (4).

HIV counseling and testing has been shown to have a role in both HIV prevention and for people with HIV infection; as an entry point to care. VCT provides people with an opportunity to learn and accept about their serostatus in confidential environment. Pregnant women who are aware of their status can prevent transmission to their infant (MTCT) (5).

Previous studies have identified certain factors associated with acceptance of HIV testing including women’s perceived risk of infection, perceived benefit and knowledge of mother to child transmission (MTCT) etc (6). This study aims to assess determining factors associated with acceptance of prenatal HIV testing.
2. Literature Review
2.1. Overview of mother-to-child transmission (MTCT)

An estimated 2.1 million children worldwide currently are living with the virus and over 630,000 children become infected with HIV in 2003, the vast majority of them acquire the virus during their mother’s pregnancy, labour and delivery or as a result of breast feeding (2). Africa is the region seriously affected by HIV/AIDS epidemic. Of ten countries worldwide with the greatest number of infected children, the top nine are all in Sub-Saharan Africa, Ranging from 140,000 in Ethiopia to 90,000 in Nigeria (7).

In most HIV infected mothers, HIV doesn't cross the placenta from mother to fetus and the placenta actually shields the fetus from HIV. This protection may break down, if a mother has viral, bacterial or parasitic placental infection during pregnancy. The greatest risk of becoming infected with HIV is during childbirth. During this single event between 10 and 20% will become infected by sucking, swallowing or aspiration of maternal blood or cervical secretion that contain HIV. Although the viral concentration in breast milk are significantly lower than those found in blood, on average about 15% of babies born to HIV infected mothers will become infected through sustained breast feeding (24 month or more) (8).

A study in women and infant, reported that a probability of 27% for in utero transmission in the USA, while in Kinshasa 23% infants were thought to be infected in utero, 65% intrapartum or early postpartum and 12% in late postpartum (9).
In low and middle income countries there is at least a 30% likelihood that an HIV positive breast feeding mother will pass the virus to her new born. From a study in Kenya and Malawi the absolute transmission rates from breast feeding were estimated to be 3.5% at 6 months, 7% at 12 months and 10.3% at 24 months (10).

The contribution of each of these routes to overall transmission has not been quantified exactly but it appears that in utero transmission is less frequently, and substantial proportion occurs at the time of delivery or late in pregnancy (9).

2.2. Prevalence of HIV infection among pregnant women

Southern Africa remains the worst affected region in the world. Data from antenatal clinics in urban area in 2002 showed that HIV prevalence of over 25% following a rapid increase from just 5% in 1990. In Swaziland the average prevalence among pregnant women was 39% in 2002 showing an increase from 34% in 2000 and only 4% in 1992. In Botswana antenatal prevalence has been sustained between 35 and 37% in the period 2001-2003 (11).

In Kenya, Malawi, Namibia, Rwanda, South Africa, the United Republic of Tanzania, Zambia, and Zimbabwe, over 10% of women attending antenatal clinic in urban areas were reported to be HIV positive, with a rate of almost 60% in some sites. In Thailand prevalence among women in antenatal clinics has climbed from 0% in 1989 to 2.3% in 1995 and continues to rise. Similar increases were reported from some Indian cities, Latin America and the Caribbean (9).
The prevalence of HIV infection among pregnant women in Ethiopia were found to be 17.8%, 17.5% and 15.1% in 1996, 1997 and 1999 respectively yielding an average of 16.8%. In urban Ethiopia the average prevalence of HIV among pregnant women are estimated to be 13% and in rural around 5% (4).

In some places HIV prevalence among pregnant women has shown a decline. The prevalence of HIV among pregnant women is high in most African countries even if it seems to decline in some parts of the region. In Addis Ababa, prevalence has fallen from a peak of 24% in 1995 to 11% in 2003 (11). In urban Uganda there has been a reported decrease in the prevalence of HIV infection, which is thought to be due to behavioral change following aggressive AIDS education (9).

2.3. Knowledge about HIV and MTCT

In a study investigating knowledge and awareness of HIV/ AIDS among pregnant women in Maharashtra State, (India) about 81% of the 269 study subjects heard about sickness called HIV or AIDS. When asked ways of spread 54% reported they did not know, 39% reported that sexual contact, 18% mentioned thorough injection, and 8% through blood, 4% mentioned commercial sex workers and only one person said from mother to child. The study reported that education played the most important role on the knowledge about HIV/AIDS (13).

Among antenatal care attending Ghanaian pregnant women at two polyclinics in Accra, less than 3% of them spontaneously mentioned MTCT as an HIV transmission route, when prompted. Majority of mothers agreed that the virus could be transmitted during pregnancy (94%), delivery
(91%), and breast feeding (86%). About 40% of the participants indicated that MTCT could not be prevented and another 14% did not know how to curtail MTCT (14).

The finding of the behavioral survey surveillance (BSS) Ethiopia 2002 about knowledge of mode of transmission of HIV, majority of the study participants mentioned unprotected sex and contaminated sharps. Only few youth participants mentioned mother-to-child transmission during pregnancy and breast feeding (19).

A community based study on knowledge, attitude and practice (KAP) on HIV/AIDS in Gambella town, western Ethiopia, indicated only 4.5% of the participants reported that they didn't heard of HIV/AIDS. The commonly reported ways of transmission were unprotected sex (79.8%) and unsafe blood transfusion (64.2%) and less than 1% reported that they know that HIV is transmitted from mother to child (15).

A community based study in Addis Ababa indicated every body has heared of HIV/AIDS. Every body knows it is transmitted sexually and through sharing contaminated cutting piercing instrument. Blood transfusion and mother-to-child transmission of the virus were mentioned by about a quarter of the informants both spontaneously and after probing. The study reported a gap in this area (16).

**2.4. Acceptance of VCT among pregnant women**

Knowledge of HIV status is a gateway to AIDS treatment and has documented prevention benefits, however the current reaching of HIV testing service is poor and up take is often low because of several factors (11).
According to the findings of behavioral surveillance survey (BSS, 2000), about 47% of the uniformed service respondents, 36% of bus drivers, 35% of minibus, 31% of commercial sex workers, 29% of youth, 11% of farmers and about 1.4% of the pastoralists reported that they knew the availability of VCT in their community. Regarding previous HIV testing experience very few of the study participants had HIV testing in the past, with the exception of uniformed service personnel (20%). In the other groups less than 11% had HIV testing in the past.

Majority of the respondents who had HIV testing in the past said the test was voluntary and, almost all study participants were willing to be tested in the future (19).

A cross-sectional mailing survey about acceptability of VCT and various MTCT interventions in antenatal clinics in 13 countries, it was reported that the median overall acceptability was 65% ranging from 33% to 95% (20).

In a study evaluated the acceptance of VCT by pregnant women in 14 urban sites in Africa and Thailand in 1997, the acceptance rate of VCT were high; median being 92% ranging from 77 to 99.7%. Over all acceptability of VCT (i.e. women coming for both test and result) was about 69%. The most common reasons to refuse testing were need to discuss with partner, fear of HIV positive status, and fear of loss of marital security, domestic violence and confidentiality. The study has also reported that better-educated women refuse to test more often than others (21).

A study from Zambia examined the readiness to utilize VCT service offered to 4812 participants from rural and urban sites. Although 37% initially expressed willingness to use VCT service, only 3.6% actually come for VCT. In Zimbabwe 186 women attending an antenatal care were
offered VCT as part of their antenatal care, although most women endorsed the multiple benefit of VCT, uptake was low, with only 23% of women consenting to VCT (20). Preliminary result from a large MTCT program in Botswana shows a relatively low uptake of VCT during the first eight months of operation (20).

A community based study conducted in Addis Ababa to assess factors influencing the use of VCT service revealed that the majority of the respondents expressed their intention to test but the practice was non-existent(16). Another community based study in Harar among 15-49 years showed that 85% of the respondents have intention of having VCT (17). A much higher level of (92%) of intention to use the service was reported from a study conducted in Dire Dawa (18).

Although VCT during pregnancy is acceptable in principle, much will have to be done to increase the utilization of the service.

2.5. Impacts of voluntary HIV counseling and testing.
The primary aim of VCT is preventive, to help people change their sexual behavior, so as to avoid transmitting HIV to sexual partner if seropositive, or to remain seronegative if negative. Many studies showed change in reported sexual behavior following HIV testing (20).

A study from TASO counseling service showed a good understanding of safer sex and higher level of safer sex behaviour following VCT. Among seropositive people 56% of females and 20% of males responded they were abstained, and 26% of females and 48% of males said they used
condoms . Of those who said they were using condoms 81.3% said that they had done so after counseling (20).

In most recent evaluation of TASO 12,120 records of clients attending VCT between 1997-1999, condom use increased from 23 to 41% for women and 20 to 49% for men following VCT. Further increase in condom use were seen in people who had further post-test counseling session (20).

Another study from Kara counseling service in Zambia, demonstrated some change in sexual behavior following VCT. Following VCT both those HIV seropostive and sero negative were more likely to use condom and reduced their number of casual sexual partners, when compared with reported behaviour prior to testing (20).

A multi-center VCT efficacy study in the United Republic of Tanzania, Kenya, Trinidad and Tobago among (3,120 and 1,534 males and 1,586 females) randomized to receive either health information or VCT showed that the percentage of individuals reported unprotected sex declined significantly. In those receiving VCT than those receiving health information only. The reduction were 35% in VCT group compared to 13% in health information group among males; and 39% in VCT group compared to 17% reduction in health information group among females (20).
2.6. Rationale of the study

Mother-to-child transmission (MTCT) is by far the largest source of HIV infection in children below the age of 15 years. The virus may be transmitted during pregnancy, childbirth, or breast-feeding (1). So far, globally 2.7 million children under the age of 15 have died of AIDS since the beginning of the epidemics. Over 9 in 10 acquire the infection from their mothers at birth or during breast feeding (22).

AIDS threatens to reverse year of steady progress in child health and survival and has already doubled infant mortality in the worst affected countries. In Sub Saharan Africa MTCT is contributing substantially to rising child mortality. In Ethiopia an estimated of 120,000 children under the age of 15 years living with the virus in 2004 (11).

For many years, little was known about preventing transmission of HIV infection from mother to child. Recently however many advances have been made in developing effective and affordable intervention that reduce the likelihood that a woman will pass HIV on her baby (2). The two most important interventions for the reduction of MTCT namely avoidance of breastfeeding and anti retroviral programs, requires a woman to know whether or not she is HIV infected in order to benefit from these interventions and other advantage of VCT (23).

The risk of HIV transmission from an infected mother to her child can be reduced by 50% by giving antiretroviral drug during pregnancy and labour and by avoiding breast-feeding. In the absence of preventive measures, the risk of a baby acquiring the virus from an infected mother ranges from 25% to 35% in developing countries (12,5).
Voluntary HIV counseling and testing (VCT) for pregnant women is a starting point for instituting a mother to child transmission (MTCT) prevention program. This strategy promotes adequate treatment for HIV positive women and has a positive impact on mother-to-child (MTCT) HIV transmission rate. For HIV negative women it provides opportunity for education and behavioral change (10, 11). But experience to-date in many countries show great variation in willingness to make use of the service that are available (23).

Many, but not all women accept VCT. The services have been slow to gain acceptance. There are many reasons why a woman may refuse VCT and understanding of those factors could help intervention design to promote VCT among pregnant women (24).

This study is therefore designed primarily to identify the factors determining acceptance of voluntary HIV testing among pregnant women attending antenatal care. The result would be useful in helping health care providers to introduce measures that could improve the utilization of antenatal HIV testing.
3. OBJECTIVES OF THE STUDY

3.1. General objective

- To identify factors determining acceptance of voluntary HIV testing, among pregnant women attending antenatal care at Armed Force hospitals in Addis Ababa.

3.2. Specific objectives

- To assess some of the demographic factors among acceptors and non-acceptors of HIV testing.
- To compare knowledge about HIV, MTCT, AND PMTCT among acceptors and non-acceptors of HIV testing.
- To assess some of the factors associated with acceptance of voluntary HIV testing among pregnant women.
- Based on the study finding to forward recommendation for policy makers and service providers.
4. Materials and Method

4.1. Study Area

The study area were two army hospitals located in the capital Addis Ababa which serve as a referral hospital to all army health institutions through out the country, the two hospitals provide different services including HIV VCT service to the army members, to civilian working in the army and their families. The maternal and child health care unit (MCH) provides PMTCT service to pregnant women attending antenatal care free of charge, it includes antenatal, intrapartum and postnatal care, family planning and STI service, voluntary confidential counseling and testing, anti-retroviral drug therapy for prevention of MTCT and pre and post test counseling. The service was started in April 2004 with six counselors in the two institution; to date more than one thousand pregnant women were counseled and about 400 tested for HIV.

4.2. Study design:

The study design was unmatched case-control.

Cases: - Antenatal care followers counseled and tested for HIV in the current pregnancy, prior to and during the study period.

Controls: - Antenatal care followers counseled but not tested for HIV in the current pregnancy, prior to and during the study period.

Inclusion Criteria

Pregnant mother who had voluntary HIV counseling in the current pregnancy.

Those pregnant women who had HIV counseling in the two hospitals.

Those pregnant women are above 18 years old.
Exclusion criteria

Those pregnant women who don't have HIV counseling

Those who had received HIV VCT elsewhere

Those who refuse to participate

Those below 18 year old and

Those who are unable to communicate for different reasons.

4.3. Sample Size

Sample size was determined using the formula for the difference between two population proportions by considering one variable assumed to bring difference in the two groups.

\[
\begin{align*}
n_1 &= \left[ \frac{z_{\alpha/2} \sqrt{\frac{1}{r} + \frac{1}{r}}} {p(1-p)} + \frac{\sqrt{p_1(1-p_1) + p_2(1-p_2)}} {r} \right] \left( \frac{1}{p_1-p_2} \right) \\
&= \left( \frac{z_{\alpha/2} \sqrt{\frac{1}{r} + \frac{1}{r}}} {p(1-p)} + \frac{\sqrt{p_1(1-p_1) + p_2(1-p_2)}} {r} \right) \\
&= \left( \frac{z_{\alpha/2} \sqrt{\frac{1}{r} + \frac{1}{r}}} {p(1-p)} + \frac{\sqrt{p_1(1-p_1) + p_2(1-p_2)}} {r} \right) \left( \frac{1}{P_1-p_2} \right)
\end{align*}
\]

Where \(n_1\) = the sample size for case

\(z_{\alpha/2}\) = critical value = 1.96

\(z_\beta\) = power of the study = 80%

\(p_1\) = estimated exposure among cases

\(p_2\) = estimated exposure among control

\(p\) = pooled estimate of \(p_1\) and \(p_2\)

\(r\) = ratio of \(n_2\) to \(n_1\)
In this study education was the variable used to calculate the sample size with an estimated exposure among cases 60% and 40% among controls with 5% marginal error and 95% confidence interval. Two controls were taken for each case to increase the power of the study. Accordingly 88 cases and 176 controls were needed.

4.4. Sampling procedure

Study subjects were pregnant women attending army hospitals mother and child health care (MCH) unit, for antenatal care follow up who had voluntary HIV counseling irrespective of their testing. Subjects were identified based on the information obtained from the client card and the clients information about whether they were tested or not. This study had two groups of subjects, the first group includes pregnant women who were tested for HIV in the current pregnancy, and the second comprise pregnant women who refuse HIV testing in the current pregnancy. Cases and controls were selected from both hospitals consecutively. Two controls were selected, consecutively immediately after one case is identified and interviewed. The procedure continued through out the data collection period until the required sample size was achieved.

4.5. Data Collection Procedure.

Data was collected from study subjects, using pre-tested structured questionnaire. The questionnaire was developed in English and translated to Amharic and then back to English to check for its consistency.

Four data collectors and two supervisors who have diploma, and who can speak Amharic and English language were recruited. The interviewers were nurses working in the MCH unit of the two hospitals and, there were two supervisors one working as general nurse from other institution and the second supervisor a diploma holder working at the VCT center of Armed force general hospital. The responsibility of the data collectors was to fill questionnaires
after obtaining verbal consent of the subjects. The supervisors provide all items necessary for data collection on each
data collection day, checking filled questionnaire for completeness, solve problems raised during data collection.

Data collection was done at one corner of the MCH unit after a woman has completed the antenatal follow up
examination.

To assure the quality of the data, properly designed data collocation tool was prepared, training were given to data
collectors and supervisor, and on each data collection day some percent of the collected data reviewed by principal
investigator, any problem faced in the time of data collection discussed and immediate solution were made.
4.6. Study Variables
4.6.1. Dependent variable

- Acceptance of voluntary HIV testing

4.6.2. Independent variables

- Age

- Educational status

- Partners residence

- Marital status

- Income

- Religion

- Ethnicity

- Number of pregnancy

- Number of ANC visits

- Knowledge about HIV, MTCT and VCT

- Perceived benefit of VCT

- Perceived risk of HIV
4. 6. 3. Conceptual framework of Voluntary Counseling and Testing (VCT)

Personal factor
- Socio-demographics
- Knowledge
- Attitude
- Perceived benefit
- Previous sexual behavior
- Perceived consequence of test
- Knowledge on VCT

Institutional Factor
- Availability
- Accessibility

Professional factor
- Attitude
- Confidentiality

Societal Factor
- Stigma
- Discrimination

Acceptance of voluntary counseling and testing (VCT)
4.7. Operational Definition

- Acceptance of VCT: - Voluntary uptake of HIV testing by pregnant women after counseling.
- Acceptors: - Pregnant women who had HIV counseling and testing in the current pregnancy.
- Non-acceptors: - Pregnant women who had HIV counseling and refuse to take the test during the current pregnancy.
- HIV Counseling: - a confidential dialogue between a person and care provider aimed at enabling the person to cope with stress and make personal decision to take the test.
- Voluntary HIV testing: - a process of voluntary HIV testing after informed consent.
- Knowledge: - Information stored in the memory related to HIV/AIDS and Mother to Child Transmission.
- Attitude: - Predisposition to respond in favorable or unfavorable manner towards HIV/AIDS and VCT.
- Perceived benefit: - outcome expectation from taking HIV test.
- Risk perception for HIV/AIDS: - Respondents feeling of vulnerability for HIV/AIDS.

4.8. Data Entry and Analysis

The data obtained from each study participant cleaned, edited and data was entered and analyzed using the epiinfo and SPSS computer software packages. Frequency distribution and cross tabulation were made for the variables, odds ratio and 95% confidence interval calculated.

4.9. Ethical consideration

Ethical clearance to conduct the study obtained from Addis Ababa University, medical faculty and permission to conduct the study in the army hospitals secured from the respective hospitals. Informed consent from each study subjects were obtained after clear explanation about the purpose of the study. Confidentiality of the information assured by omitting names of study
subjects from the questionnaire and maximum effort made to maintain privacy of the respondent during the interview. No question was asked about their serostatus and information was provided on the benefit of knowing their serostatus and about availability of drugs and intervention that reduce the risk of mother to child transmission of HIV infection for those mothers who refuse to take the test. The data collection procedure was not harmful to study participants and data collectors.
5. Results

A total of 264 pregnant women attending antenatal clinics were included in the study. Among the studied women 88 were voluntary acceptors of HIV counseling and testing (cases), and 176 were non-acceptors of voluntary HIV testing (controls).

Majority of the acceptors as well as non-acceptors of HIV testing were between 20 and 29 years. The median age of women among acceptors was 25.7 years and 26.2 years for non-acceptor. Majority of the study subjects were married, (99.7% of acceptors and 88.1% of non-acceptors). About 84.9% of acceptors and 43.2% of non-acceptors lived with their husbands. Almost equal proportion of acceptors and non-acceptors of voluntary HIV testing were unemployed (72.9% vs. 76.5% for acceptors and non-acceptors respectively). Amhara ethnic group comprises the largest proportion of the study subjects (47.7% vs. 36.4%), followed by Tigrie (27.3% vs. 33.5%) and Oromo (15.9% vs. 22.1%) for acceptors and non-acceptors of HIV testing respectively. (Table1)

Table 1 also shows that more than 80% of acceptors and non-acceptors respectively were followers of orthodox Christian religion.

Prior HIV testing had been performed by 27.3% of acceptors and 15.3% of non-acceptors of VCT, but there is no difference in socio-demographic characteristics of acceptors and non-acceptors of the test. There was lower level of perceived risk to HIV/AIDS in both groups (34.1% for acceptors and 29.6% for non-acceptors of VCT). On the other hand 92.0% of acceptors and 79.5 of non-acceptors of VCT perceived the benefit of the test to mother and baby. (Table 2)

As shown in Table 2 about 38.6% of acceptors and 33.5% of non-acceptors had two pregnancies including the current one. Most women, (86.4% of acceptors and 69.9% of non-acceptors) had at least two antenatal visits during the current pregnancy.

As shown in Table 3 about 99% of the acceptors and 97% of non-acceptors mentioned sexual contact, 75% of acceptors and 85% of non-acceptors mentioned that contaminated blood and blood product and 86% of acceptors and 88% of non-acceptors contaminated sharps as a main route of HIV transmission respectively. MTCT was mentioned by relatively lower proportion of acceptors and non-acceptors of VCT (77% and 37% respectively).

About the time when MTCT could occur, most acceptors and non-acceptors of VCT mentioned transmission of the virus during delivery and breast-feeding. Lower proportion of acceptors (39%) and non-acceptors (25%) mentioned that MTCT occur during pregnancy. Regarding to intervention to reduce MTCT, about 95% of acceptors and 84.1% non-acceptors mentioned that they know about intervention that reduce MTCT. (Table 3).

When asked questions on how to reduce the risk of MTCT, 92% of acceptors and 77% of non-acceptors mentioned use of antiretroviral drug and 39% of acceptors and 22% of non-acceptors mentioned avoidance of breast-feeding as a means of reducing MTCT. (Table 3)

Table 5 shows socio-demographic factors associated with voluntary acceptance of HIV antibody testing. Acceptance of VCT was slightly higher in the older age group 30-39 years compared to younger ages, but was not statistically significant.

Married women were more likely to accept VCT compared to those who were not married (OR=5.83, 95% CI=1.25, 36.38). Similarly among married women those who were living with their husbands were more likely to be tested compared to those whose partners lived away (OR=7.38, 95% CI=3.65, 15.23).

As shown in table 5, the odds of accepting VCT significantly increased with an education level. Women with secondary and tertiary education were 3-5 times more likely to accept VCT than those who were illiterate and with primary education. The odds of VCT acceptance was also higher in the higher income group (OR= 2.88, 95% CI= 1.43,5.84).

Other variables like religion and ethnic group of the mother were not found associated with the acceptance of voluntary HIV testing

As shown on table 6 the number of antenatal visits attended by mothers were also analyze to look for association of antenatal visit and acceptance of VCT. Women who attended at least two antenatal visits were more likely to take the test compared to those mother who attended less than two visit (OR=2.73, 95% CI=1.13,5.78).

The women were also compared with respect to their previous HIV testing experience. Mothers who had HIV testing in the past for different reasons were about 2 times more likely to accept voluntary HIV testing in the current pregnancy compared to their counter parts (OR= 2.01, 95% CI=1.03, 3.95).(Table 6)

Women who knew existence of intervention that reduce the risk of MTCT of HIV infection were also about 3 times more likely to practice VCT compared to those who were not (OR=3.26, 95 CI= 1.02,11.55). Those women who perceived the test beneficial to women and her baby were also 3 times more likely to be tested (OR=3.01, 95% CI=1.24, 7.96) (Table 6).

Study participants were also assessed about their knowledge of route of HIV transmission, when mother to child transmission could occur and about attributes in the prevention of mother to child transmission of HIV infection. Both groups mention means of transmission of HIV like sexual intercourse, blood and blood product, contaminated sharp instruments & mother to child transmission (MTCT), but the proportion of women who indicated MTCT was higher among women who were tested (77.2%) as compared to those who were not tested (37.5%) the difference being statistically significant [P.<0.001].

Mothers who said MTCT could occur during pregnancy were about 1.8 times more likely to be tested (OR=1.89, 95% CI =1.05, 3.39), and those who said avoidance of breast feeding as a means of intervention to reduce MTCT were about 2 times more likely to accept the test than those who didn’t (OR=1.90, 95% CI=1.06, 3.49).

Variables like education, marital status, residence of the husband, income, number of antenatal visits, prior HIV testing, awareness of intervention that reduce MTCT, knowing MTCT as route of HIV transmission, and perceived benefit of the test were entered for multivariate analysis. The strongest association with acceptance of VCT rested with husbands residence, knowing MTCT as route of HIV transmission and prior HIV testing experience. Women who lived with their husbands were about 5 times more likely to be tested than those whose husband lived away (95% CI=2.15,11.46), and also those who knew MTCT as route of HIV transmission were 7 times more likely to be tested (95% CI = 3.44,15.67).(Table 8)

As shown on table 8 being tested for HIV in the past also appeared as an independent factor positively influencing acceptances of HIV testing, women who had prior HIV testing were about 2.5 times more likely to be tested than those who had no prior HIV testing.

6. Discussion

Nowadays antiretroviral drugs for prevention of mother to child transmission (MTCT) of HIV infection become available in developing countries. For a pregnant mother to benefit from this intervention, she needs to know her serostatus. Voluntary HIV counseling and testing (VCT) provides an opportunity to know her status and serve as an entry point to make decision on use of the intervention to reduce mother-to-child transmission of HIV infection.

Our study shows that higher level of education (secondary and tertiary) of the mother strongly associated with acceptance of voluntary HIV testing. The result of this study is consistent with the findings from other studies. A study from Hong Kong reported that level of education was significantly associated with the acceptance of HIV testing (1). Another study conducted in urban and rural areas in Zambia, reported that HIV test rate increases with increasing educational attainment, about three to four times higher when contrasting the two extreme levels of education (25). Also a study conducted in Zambia showed in the more educated, the higher the HIV test rate, the odds ratio between the two most extreme level of education (<8 years vs. >12 years of schooling) was (OR=3.4, 95% CI, 1.33, 8.83) (26). But in one study done among pregnant women in Dar-es-salaam, Tanzania, higher level of education of the mother was associated with decreased acceptance of testing (27). The association of acceptance of testing and education can be explained by the fact that educated mothers are better in assessing the advantage of testing and may be aware of the benefits of the test and treatment options that reduce mother to child transmission of HIV infection.

This study also revealed that income is associated with acceptance of HIV testing, in our data set this can be seen in the increasing testing with increasing income of the household. This finding,
however, disagree with a study from Tanzania, that showed association of higher socio-economic status with significant increasing refusal of HIV testing (27). In a study among Rwandans showed that women whose partners had well-paid job were about four times more likely than their counterparts to accept HIV testing (6).

The analysis of marital status and acceptance of voluntary HIV testing showed that married women were more likely to be tested than unmarried women (OR=5.83, P.<0.01). This finding is not supported by findings of other studies. A study from Tanzania showed women cohabitating while unmarried were significantly more likely to be tested than married mothers (P=0.03) (27). Another study conducted in Barbados that assessed association of marital status and acceptance of testing, showed that single women were less likely to refuse HIV testing than married women, but the association was not statistically significant (28). The association of marriage and acceptance of HIV testing in this study may be due to the fact that married women are more confident that they are at less risk compared to unmarried because of their committed marriage.

Our results showed that pregnant women who were living with their husbands were significantly more likely to be tested than those pregnant women whose husbands lived another place for various reasons. Adjusted for other demographic and reproductive characteristics, on multivariate analysis partner at home was significantly and independently associated with VCT acceptance. A study which assessed effect of partner involvement and couple counseling on the uptake of intervention to prevent HIV transmission among women attending antenatal clinic in Nairobi, reported that the importance of partner participation as a significant factor for VCT. (29).

Also a study conducted in India reported that about 46% of the women mentioned their husband as a primary decision maker in issues like voluntary HIV counseling and testing (32). The
possible explanation for association between husbands residence and acceptance of prenatal HIV testing may be women who are living with their husbands are more likely to discuss the issue of voluntary HIV counseling and testing, decide whether to be tested or not. Moreover they may have their husbands support and even the possibility for the couples to take VCT, unlike those pregnant women whose partner live away.

In this study less proportion of the study subjects consider themselves to be at risk of getting HIV/AIDS (34.% for acceptors and 29.6% for non-acceptors of HIV testing). Similar finding were reported from studies conducted in Dire Dawa among pregnant women, which was about 24.8% (18). A community based studies conducted in Assossa on acceptability of voluntary counseling and testing and in another study conducted in three sites(Addis Ababa, Arsi, and Debre Berhan)on perception of risk and vulnerability to HIV/AIDS reported similar finding.(33,34)Perceived risk of getting HIV was not found associated with acceptance of HIV testing.

This study showed pregnant women who had HIV testing in the past were twice more likely to be tested than those women who had no prior HIV testing experience. When adjusted for other variables prior HIV testing experience was independently and significantly associated with VCT acceptance. This finding was also reported by other studies. A study conducted in Zambia indicated that having HIV test in the past was an independent factor positively influencing readiness for testing (26), and a study from Barbados showed women who had had a prior HIV test were less likely to refuse HIV testing during the current pregnancy when compared to women who had no prior HIV testing (28). The possible explanation for association between previous testing and current one is that women who had HIV testing in the past are more likely to
have change in their sexual behaviour after knowing their serostatus. This was shown by studies that assessed behavioral change following HIV VCT. As a result women who were tested in the past are more likely to take the test considering their previous test result and and the change in their sexual behaviour and thinking the outcome of the current test to be negative.

Unlike the studies conducted in Zambia and Tanzania in this study age of the mother was not found associated with the acceptance of HIV testing. A study done in Zambia showed test rate were lowest among adolescents, while a study in Tanzania indicated old age were associated with decreased screening acceptance, which is also inconsistent with previous studies that showed association of old age with both decreased and increased test acceptance (25,27).

Our finding on the association of knowledge of existence of intervention that reduces mother-to-child transmission of HIV and acceptance of voluntary HIV testing agree with findings from other studies. In our study pregnant women who know existence of intervention that reduce mother-to-child transmission of HIV were about 3.2 times more likely to be tested than those who were not aware of intervention to reduce MTCT. In two other studies knowledge about treatment that reduces mother-to-child transmission of HIV was found independently associated with testing. A study conducted in the USA to determine whether the knowledge of Zidovudine treatment to reduce the risk of MTCT showed increase of the likelihood of HIV testing among pregnant women of child bearing age and among pregnant women receiving prenatal care. Majority of the study participant from both surveys reported that they were more likely to take a test for HIV knowing about Zidovudine treatment (31).

In this study there was no association between number of pregnancy a woman had, including the current one, and acceptance of voluntary prenatal HIV testing. This finding is consistent with a
study conducted in Rwanda (6). The finding of this study also showed significant association between the number of antenatal visit and acceptance of prenatal HIV testing. Mothers who had two or more antenatal visits were more likely to be tested than those who had less visits (P=0.01). This association between number of antenatal visit and acceptance of prenatal HIV testing may be explained by frequent exposure of mothers to information regarding HIV, MTCT and PMTCT during their follow up, which may influence the mother to take the test.

This study showed that perceived benefit of HIV testing was found to be significantly associated with the acceptance of prenatal HIV testing (OR=3.08), similar to the study conducted in Hong Kong (1).

In our study knowledge of mother-to-child transmission as a route of HIV transmission during pregnancy, and avoidance of breast-feeding as a means to reduce mother-to-child transmission of the virus were found significantly associated with the acceptance of VCT. When adjusted for other factors the association between knowledge of MTCT and VCT acceptance was even stronger (OR= 7.34, 95% CI= 3.44, 15.67). Similar findings were also reported by a study from South Africa (30).

Almost all pregnant women in this study heard about VCT from different information sources, but the source of information was not found associated with acceptance of VCT. In a study conducted in Hong Kong acceptance of HIV testing was strongly associated with access to information, that reported pregnant women who got information from one or two source were about 4 times more likely to accept the test than those who had no access to information, and those who had from three or more sources were associated with even higher acceptance (1).
7. **Strength and limitation of the study**

**Strength**

There was no study conducted using case control study design in this institution or other institution, and this study will provide information or clue to similar studies that are going to be conducted in the future. Multiple logistic regression was done to control the effect of the variables in the study.

**Limitation**

The limitation of this study were small sample size of the study participants and generalizability of the study, besides there was no local or a study from Africa using case control study design for comparison.
8. Conclusion and recommendation

8.1 Conclusion
Our study which was conducted among pregnant women attending antenatal care in two army hospitals to determine factors associated with acceptance of antenatal HIV testing has reached to the following conclusions.

- Women who had secondary and tertiary education are more likely to accept VCT, than those who are illiterate or with primary education.
- Pregnant mothers who are married and live with their partners (husbands) are more likely to accept HIV testing.
- Pregnant mothers, who had prior HIV testing, accept antenatal HIV testing than those mothers who had no prior testing.
- Pregnant women who knew existence of intervention that reduce MTCT and acknowledge benefits of VCT are more likely to take antenatal HIV testing.
- Pregnant women who knew MTCT as route of HIV transmission, and those who mentioned avoidance of breast feeding as a means of PMTCT are more likely to take prenatal HIV testing.
- Adjusted for demographic and some reproductive characteristics, women whose husbands live at home, who had better knowledge of MTCT and those who had prior VCT experience were more likely to undertake VCT than their counterparts.
8.2 Recommendation

- Based on the finding of this study we recommend on the need for intensive and continued education, to both pregnant mother and their partners, about prenatal HIV transmission, the role of voluntary HIV counseling and testing (VCT) on the prevention of mother-to-child transmission of the virus, and about the existence of intervention that reduce the possibility of prenatal transmission of the virus, with especial emphasis to those couples who live apart, due to the nature of their job (eg. military).

- The use of various means of information to access for all the target population is also recommended.

- Increasing women education to the highest possible level

   2. VCT non acceptors

Introduction
   My name is ______________________________ I am interviewing pregnant women attending antenatal clinic at__________________________ (name of institution) about factors affecting acceptance of voluntary HIV testing among pregnant women.
   The interview should be conducted after a woman passes through the process of voluntary counseling whether she accept HIV testing or not.
   I am going to ask you some question about voluntary HIV counseling and testing, your responses are completely confidential; your name will not be written on the form and will never be used in connection with any of the information you provide. You don’t have to answer any question you don’t want to answer, however your honest answer to this question will help us to understand factors affecting acceptance of voluntary HIV counseling and testing. We would like to thank you in advance for your help, are you willing to participate.

   If yes-(1) continue
                  No-(2) stop

**Questions:**

1. What is the range of temperature?
2. What is the range of time?
3. What is the range of pressure?
4. What is the range of humidity?
5. What is the range of salinity?

**Values:**

1. ≤ 19
2. 20-29
3. 30-39
4. 40
5. > 40

**Options:**

1. Yes
2. No
3. Maybe
4. Unknown
